Table of Contents

Location, Access and Topography

The Pillars property is located in Walters and Leduc Townships approximately 25 kilometres northeast of the town of Beardmore, Ontario. It is situated approximately 4km east of the east side of Highway 801 at kilometre marker 3 and covers the area north and east of Nissiamkikam Lake. The approximate centre of the Property is at 455000/5504000 (UTM; NAD83). Access to the property can be gained by walking 4km along a cut line east from kilometre marker 3 on Highway 801 or via a road emanating off of Highway 11 (456890/5503090) trending north and then west.

The property falls under Mining Lease 107144 which consists of the following dispositions: TB222655, TB222656, TB377993 and TB222661. For the purposes of this report, mining Claims # 835326, 835327, 845846 and 845847 (registered under Sage Gold Inc.) also fall under the definition of the Pillars property. Table 1 summarized the status of the land comprising the Pillars property.

The property overlies an area of mostly subdued topography with variable amounts of cedar & spruce swamp and pine-spruce forest. North-south and northwest-southeast trending valleys are likely related to late brittle faults. Overburden (sands and silts) is minor in most areas of the property while outcrop is moderately abundant comprising 5-10% of the area.

Note that the 'Pillars property' covers the area shown in Figure 2 and should not be confused with the 'King Solomon's Pillars' property located to the west and covered in a separate report.

History

As described in an internal INCO report, the Pillars property has seen the following exploration:

1934: Dumond Mining and Exploration completed a program of prospecting and trenching.

1935: Mr. J.H.C. Waite optioned the property. He completed an extensive surface exploration program including diamond drilling. A mineralized zone 154 ft long by 7 ft wide grading 0.34 opt Au was outlined on surface.

1936: Oremond Gold Mines sank an exploration shaft to a depth of 300 ft and levels were established at 150 and 275 ft. A total of 3,024 ft of drifting was completed.

1940s: McLeod Cockshutt Gold Mines completed some diamond drilling.

1963: Two individuals acquired the property and completed a program of reconnaissance geological mapping, sampling and drilling.

1968: Solomon's Pillars Gold Mines Limited acquired the property. They dewatered the shaft, did an underground sampling program, surface EM, magnetics and geology surveys and completed six diamond drill holes totaling 806.2 ft. In general, the underground sampling returned values of up to 0.50 opt Au across narrow widths. The best mineralization located is at the east end of the 150 ft level drift where a mineralized quartz vein averaged 0.23 opt across 10.1 ft.

1968: The claims lapsed and Canadian Nickel staked the property. A grid was cut and a reconnaissance geological survey completed.

1974: The grid was recut and magnetics, VLEM and geology surveys completed, as well as some surface sampling. Eleven holes totaling 1,917 ft were drilled. Drilling narrowed down the zone of interest to between 4+00E and 16+00E. The best intersection was 0.249 opt Au across 22.9 ft. Surface sampling from the West Zone returned 0.386 opt Au across 5 ft.

1975: Thirteen holes totaling 3,894 ft were drilled to trace mineralization previously located. Drill results returned values over narrow widths with the best intersection being 0.115 opt Au across 5.1 ft from the West Zone. A resource calculation was completed which outlined 275,892 tons grading 0.126 opt Au to a depth of 300 ft for the West and Main Zones.

1982: The property was optioned to Lynx Canada Exploration. Surface sampling and line cutting were carried out before the option was dropped.

1985: A joint venture was formed with Pronto Explorations Limited.

1986: Nine holes totaling 2,436 ft were drilled to test the Main Zone. This drilling indicated the Main Zone to be 1 to 16 ft thick, 130 ft deep with a strike length of at least 700 ft and a 15^{o} east plunge. The best drill intersection is 0.240 opt Au across 14.4 ft from the Main Zone.

1987: Ten holes totaling 6,022 ft were drilled to test the down-plunge extension of the Main Zone and the West Zone. The most significant intersections are 0.362 opt Au across 5.0 ft from the Main Zone and 0.712 opt Au across 1.6 ft from the West Zone. The grid was extended to cover those portions previously not covered and magnetometer and geology surveys completed. An additional twelve holes totaling 8,074 ft were drilled. The best intersections are 0.14 opt Au across 4.5 ft from the West Zone and 0.189 opt Au across 5.0 ft from the east end of the property.

1988: One hole totaling 1,607 ft was drilled to undercut the Main Zone. The hole never reached its target and no values of note were intersected.

2008: Kodiak completed channel sampling and an approximately 5000 metre drilling program in 23 holes. Details regarding this program were not publically available at the time this report was prepared.

Geology & Mineralization

Regional Geology

The Pillars property is situated in the northern part of the Southern Sedimentary Unit (Lafrance *et al*., 2004); one of three metasedimentary panels that combined with three intercalated metavolcanic units constitutes the Beardmore-Geraldton Belt. Numerous gold mines and prospects are known in this belt including the Leitch (850,000 ounces gold), Sand River (50,000 ounces gold) and the King Solomon's Pillars shaft (unknown history) on the western part of the Pillars property.

Property Geology

Lithologies

The main lithotypes on the property are discussed below. Iron formation is rare, occurring only in the central part of the property.

Iron Formation

As summarized from Perry (1986):

The iron formation is composed of a fine grained to very fine grained, laminated to thinly bedded intercalated sequence of dark brick red hematite and jasper, dark charcoal gray to black magnetite and specular hematite in varying proportions. Thin laminated to bedded iron formation sequences vary in thickness from one to two centimetres to tens of centimetres and are intercalated with metasediments, mainly graywackes. The iron formation is very steeply dipping (generally greater than 85 degrees north to south). The jasper-hematite content remains relatively constant through the formation. The northern contact of the iron formation with the metasediments is relatively sharp while the southern contact is noticeably less abrupt and is gradational over several feet from dominantly iron formation to dominantly graywacke. Thin wisps of jasper iron formation continue to occur for a few tens of feet up into the graywacke metasediments. There does not appear to be any lateral variation in the iron formation other than a change in thickness, largely due to boudinage and folding. Minor brecciation has occurred locally, partly due to faulting and partly due to quartz vein intrusions. Small cross-cutting fractures are common in many places on a scale of 1 to 3 millimetres. These fractures are commonly quartz healed but in many places they are healed by remobilized specular hematite.

Metasediments

As summarized from Perry (1986):

Well bedded sequences of metasediments occur above and below the iron formation. These metasediments are mainly graywackes in composition. There are some, minor, local beds of argillaceous greywacke, quartzite siltstones and silty iron formation. These metasediments are conformable with the iron formation. The graywackes are fine grained to very fine grained and thin bedded to laminated. Beds are commonly 30 cm or less in thickness. The degree of sorting ranges from generally good to locally very poor. Graded bedding is relatively common, with argillaceous caps preserved at the tops of graded sequences and rounded to subrounded clasts up to 3 millimetres in diameter at the base of

graded beds. These clasts appear to be mainly quartz grains in a biotite rich very fine grained matrix. Local beds of very fine grained laminated graywacke have been slightly to highly contorted and exhibit wavy and ptygmatic folds. The graywackes which occur immediately adjacent to and interbedded with the iron formation are generally very clean, fine grained and a pale yellow-green colour. They are often strongly sheared and have abundant sericite and some chlorite alteration along the shearing. In almost all cases shearing has occurred parallel to bedding. Bedding contacts are commonly sharp.

Quartz Veins

A couple of varieties of quartz veins occur on the property. The most common variety is a group of quartz-ankerite +/- specularite, pyrite, chalcopyrite and arsenopyrite. This type of vein can be found throughout the property and very rarely contains sulphides or appreciable gold values. The veins range in width from 1 cm to about 1 metre and can often be followed along strike for several 10's of metres. In rare instances (on the King Solomon's Pillars property to the west), these veins carry coarse free gold together with small amounts (<1%) of pyrite, chalcopyrite and arsenopyrite. The visible gold appears to be quite poddy, and can usually only be followed on strike for a metre or two. The veins commonly strike near parallel to the bedding plane of the surrounding metasediments and often do not show appreciable evidence of deformation. Although folding of these veins has been observed, they commonly crosscut bedding and foliations.

The second variety of quartz veining occurs within and proximal to shear zones and structurally disrupted iron formation. They are commonly deformed, contain clots and septa of chlorite-sericite altered wallrock and vary in thickness from a few 10's of centimetres to thin subcentimetre stockwork style veins. They often contain sulphides and sulphidized selvedges composed of fine grained pyrite, fine to coarse grained arsenopyrite and (minor) clotty chalcopyrite. Sulphide contents can be as high as 75%, but overall, constitute 5-10% of the vein/selvedge. Higher gold values generally correlate well with elevated sulphide contents.

Mafic Metavolcanics

A few outcrops of massive to pillowed chlorite altered basalt occur along the northern boundary of the property. They represent the southern boundary of the Central Volcanic Unit (Lafrance *et al*., 2004).

A gabbro body has been mapped by OGS in the eastern part of the property (Figure 3). The current author is not aware of any exploration conducted in this area, therefore, little is known about the intrusion.

Feldspar Porphyry

Feldspar porphyry has only been encountered in drillcore. It consists of millimetre to centimetre scale rounded to euhedral zoned feldspar crystals that can constitute up to 75% of the rock. The feldspars have been reoriented into alignment with the primary fabric and weakly-moderately altered to sericite-chlorite-epidote. They reside in a fine grained medium grey matrix of quartz, feldspar and possibly amphibole that has been silicified and sericite-chlorite altered.

Structures

D_2 deformation is responsible for the dominant fabric on the property, an 070 to 080 trending axial planar cleavage that is approximately parallel to bedding. This fabric can be found throughout the property, and is best observed in the argillite caps to graded bed sequences. The fabric parallels the axis of a regional scale F_2 synform recognized on the basis of younging directions west of the property. The F_2 fold axis largely dips steeply to the south, however, D_3 deformation has partially disturbed its orientation. Drilling west of the property (Amulet Showing, King Solomon's Pillars property) indicates (based on changes in younging directions) that the iron formation in the southern limb of the synform is tightly to isoclinally folded. This folding is most likely D_2 in age as well. The results of the ground magnetic survey and property mapping indicate that the iron formation beds are not repeated in the north limb of the syncline. The reason for this is unclear, but may relate to the faulted boundary between the southern sedimentary unit and central volcanic unit located on the northern edge of the property. The shear zones on the property near the iron formation are also D_2 in age as indicated by overprinting D_3 fabrics.

D_3 deformation is less penetrative than D_2, but is generally visible on most outcrops. The S_3 fabric occurs as a spaced cleavage oriented counterclockwise (20-30 degrees, locally 70-80 degrees) of bedding and S_2 fabrics. D_3 is responsible for west to northwest trending west plunging Z-fold axes and north-northwest trending S-kinks. A shallow (20-30 degrees) west plunging lineation is a result of the intersection of S_2 and S_3. Some of the showings on the property indicate that the mineralization's geometry is in part controlled by this shallow west plunging lineation as is the case elsewhere in the Beardmore-Geraldton Belt.

Late northwest, northeast and north trending faults are also present on the property exhibiting both dextral and sinistral offsets. Of the faults observed, offsets have not exceeded a few metres.

Mineralization

Mineralization on the property occurs in three settings.

1) Approximately 070 to 080 trending centimetre to metre scale quartz-ankerite veins with little to no sulphides but fine to coarse flecks of visible gold. Sulphides consist of pyrite, chalcopyrite and arsenopyrite but rarely constitute more than 1% of the rock. Although not documented on the Pillars property, it can be found a short distance to the west on the Golden Sceptore and Throne Showings (King Solomon's Pillars property).
2) Approximately 070 to 080 trending silica-sericite-chlorite-ankerite-pyrite-arsenopyrite altered and sheared fine-grained sediments with associated quartz veining and stockworking. The shear zones can be several metres wide and traced along strike for hundreds of metres. The main shear occurs just south of the primary iron formation unit on the property; however, these shears can also be found north of the iron formation. Sulphide and gold values vary considerably along the shear zones strike and width. Gold values are strongly associated with high sulphide contents, particularly arsenopyrite.
3) Sulphide replaced quartz veined/stockworked and often sheared oxide facies iron formation. The sulphides largely consist of fine grained pyrite and fine to coarse grained arsenopyrite and predominately occur in the iron formation rather than the quartz veins. The best mineralization appears to occur in metre-scale highly sulphidized structurally complex pods that plunge shallowly to the west.

2009 Exploration Program

Diamond Drilling

The 2009 exploration program on the Pillars property exclusively involved diamond drilling which consisted of 16 holes and 1703 total metres. Assay results from the program can be found in Appendices A & D. Drill logs and drill sections are located in Appendices B and C respectively. Details regarding collar locations, hole azimuth and dip etc are shown below in Table 2. Highlight assay results are shown in Table 3. Additional details regarding the drilling operation are located in Appendix F. The drilling was conducted by Cobra Drilling Ltd. of Thunder Bay, ON and consisted of NQ-diametre core (4.7 centimetre). The drilling was focused on the past-producing King Solomon's Pillars Mine as well as an unnamed airborne electromagnetic anomaly along the northern boundary of the property.

Drill holes 09S002 and 003 tested a linear electromagnetic anomaly identified by an airborne geophysical survey. The holes intersected greywackes of the southern sedimentary belt and mafic volcanic rocks of the central volcanic belt to the north. These two belts were in contact along a regional-scale fault with abundant graphite development and sporadic sulphide content which likely explains the electromagnetic anomalism.

09S002: This hole comprised greywackes with variable shearing, alteration, and quartz veining intensities accompanied by very minor sulphides. Structural overprint was more pervasive proximal to the contact with mafic volcanic rocks where extensive graphitic fault zones were developed with local concentrations of pyrite. Mafic volcanic rocks comprising medium-grained amphibolites were initially intersected at 140 metres and the most significant sulphides at 163 metres where concentrations were locally up to 10 % pyrite. No significant assays were returned.

09S003: Hole 09S003 was drilled in the opposite direction of 09S002 and consequently started in the mafic volcanic rocks which varied texturally from medium- to fine-grained and were extensively chloritized. Large fault zones with abundant graphite and local sulphides were also present as in 09S002 with no significant gold values returned. Sulphides were particularly concentrated from 200-230 metres where local concentrations ranged up to 35% over half metre intervals.

Drill holes 09S004, 005 and 010-021 were drilled in the vicinity of the past-producing King Solomon's Mine, aimed at mineralized iron formation and proximal sheared greywackes with gold-bearing quartz veins. The shear and mineralization intensity of the greywacke is greatest along the southern contact of the iron formation and, consequently, this is the location of the best gold grades.

09S004: Drill hole 004 was designed to scissor an encouraging intersection from the work of a previous explorer. It intersected greywacke with increasingly intense shearing and quartz veining from 19.25-20.7 m adjacent to the oxide iron formation. Intense alteration and mineralization comprised abundant sericite-epidote with pink-stained quartz veins and pyrite and arsenopyrite abundances from 5-15 % each. This mineralization returned a gold intersection of 4.09 g/t Au over 1.45 metres (Table 3). Small beds of iron formation were interbedded with greywacke; these interbeds and the principal iron

formation bed (from 23.46-42.96 metres) consisted of centimetre-scale bands of alternating quartz-magnetite-hematite.

Drill holes 09S005, 010, 020 and 021 were drilled from the same setup testing the theory of plunging ore shoots by attempting to intersect the down plunge projection of encouraging channel results from surface; the latter reported by previous workers. Varying dip angles was also meant to test the potential of multiple, stacked shoots lying along the southern contact of the iron formation.

09S005: This hole intersected variably sheared greywacke with minor mineralization in the top 30 metres giving way to an intensely sheared and veined zone down to 34.22 metres. This intersection was characterized by epidote-sericite alteration with associated quartz veins, pyrite-arsenopyrite (up to 30 and 5 % respectively) and encouraging gold values (Table 3). Several, minor zones of mineralized greywacke were intersected down hole without appreciable gold values. Twenty metres of iron formation started at 40.55 metres comprising finely bedded quartz-hematite-magnetite followed by greywacke to the bottom of the hole; significant gold values were not returned from these units.

09S010: Hole 09S010 intersected predominately greywackes with variable amounts of shearing and alteration and only minor quartz veining and sulphide mineralization. Where present, mineralization comprised quartz veins and minor pyrite-arsenopyrite (less than 2 % each) with sericite-epidote-chlorite alteration. The highest gold grade reported form 09S010 was 1.64 g/t Au over 0.65 metres from 79.25-79.9 metres from one of several iron formation beds within the bottom 20 metres of the hole.

09S020: Greywackes with minor alteration dominated the top 67 metres of this hole followed by sheared and mineralized greywacke down to 74.71 metres. This intersection contained 20-30% quartz veins with associated pyrite and arsenopyrite abundances from trace levels to 8% each. This form of mineralization was repeated at 86 metres and yielded additional gold values (Table 3). The remainder of the hole consisted of weakly to rarely altered greywacke with some iron formation interbeds in the bottom 20 metres.

09S021: The upper 30 metres of 09S021 comprised greywacke with minor amounts of alteration, shearing and quartz veining. Sulphide content increased between 30-35 meters in veined greywacke with pyrite-arsenopyrite contents up to 2% each. Two 0.35 metre samples from this zone ran 3.17 and 2.14 g/t Au respectively. An unmapped portion of the mine was apparently intersected from 36-38.4 metres, likely representing a mineralized shoot that had been mined out. The reminder of the hole contained weakly altered greywacke with more frequent iron formation beds, ending with 4 metres of oxide iron formation.

09S011: This hole was designed to intersect a theorized up-plunge projection of previous explorers drill intercepts. Weakly altered greywacke was in contact with oxide iron formation which ran from 36-42 metres. Greywackes followed north of the iron formation and remained only weakly altered. Sulphide contents never exceeded 2 % in the hole; no significant assays were returned.

Holes 09S012-017 were drilled from the same location with varying dips and azimuths. This approach was an effort to further test the idea that plunging ore shoots were present in the area, an

idea apparently not considered by previous operators and explorers. A previous explorer had reported a considerable grade-width intersection in drilling from the immediate area.

09S012: This hole was directed toward a previously reported gold interval and intersected greywacke with local sulphide mineralization for the initial 60 metres. From 60.62-65.81 metres intense alteration and sulphidization affected greywacke with minor iron formation interbeds. Pyrite and arsenopyrite were locally massive over 0.5 metre intervals within this section with associated quartz veins which returned a gold intersection of 5.75 g/t Au over 5.19 metres (Table 3). More weakly altered greywacke followed this interval followed by 10 metres of iron formation at the bottom of the hole.

09S013: Hole 09S013 was intended to intersect the up-plunge projection of the mineralization noted in 09S012. Greywacke dominated the hole which had local concentrations of sulphide up to 20% in the top 60 metres. These local areas of sulphidization produced single sample gold values up to 5.35 g/t Au over 0.35 metres. The best gold intersection comprised 3.92 g/t Au over 2.5 metres from 62.5-65 metres (Table 3) where pyrite abundances ranged as high as 40% with minor arsenopyrite. Here greywacke was dominant with significant iron formation interbeds, both with extensive chlorite and sericite alteration.

09S014: The mineralization in 09S013 was encouraging but it was felt that the thickest portion of the mineralization was not tested, for this reason 09S014 was drilled at a steeper angle along the same azimuth. Similar to 09S013, the upper 63 metres was predominately greywacke with local sulphide concentrations including a 0.43 metre section with 25 % pyrite and 7.85 g/t Au. Iron formation beds became more frequent below 63 metres as did the alteration/mineralization intensity to approximately 73 metres depth, within which pyrite contents frequently ranged greater than 10%. From this interval 4.64 g/t Au over 5.4 metres was returned (Table 3). Interbedded and faulted greywacke/iron formation comprised the remainder of the hole with only weak, local mineralization.

09S015: This hole was drilled along the same azimuth as 09S013 and 014 with a shallower dip testing for a higher level ore shoot. Greywackes were noted with moderate alteration intensities and only local sulphide concentrations. The iron formation from 32-53 metres was similar in alteration and mineralization intensity. A high assay of 2.85 g/t Au over 0.5 metre was attained from 54.45-54.95 metres.

09S016: This hole was to test the down-plunge projection of mineralization noted in 09S012, 013 and 014. It intersected weakly to moderately altered greywacke with local pyrite concentrations up to 10%. These areas occasionally produced significant, single sample gold values including 3.09 and 2.81 g/t Au at 80.1 and 84.7 metres depth respectively. Alteration and mineralization once again intensified proximal to the iron formation contact where pyrite content ranged up to 75% producing gold values of 3.41 g/t Au over 4.55 metres (Table 3). Following this intersection, the iron formation and northern greywacke were not significantly altered and returned low gold values.

09S017: The intersection in 09S016 was narrower than expected so the decision was made to shallow hole 09S017 for another test of the zone. It intersected weakly to moderately altered greywacke in the top 69 metres of the hole and sulphide-rich greywacke at the contact with iron formation at 69.83

metres which reported 6.41 g/t Au over 1.41 metres (Table 3). The hole ended with weakly altered greywacke and minor iron formation interbeds.

Drill holes 09S018 and 019 were to test the down-plunge projection of excellent gold values in surface channels reported by a previous explorer while also testing the potential of multiple, stacked ore shoots.

09S018: Poorly altered greywacke comprised the top 15 metres of the hole. The best mineralization overlapped the contact between greywacke and iron formation where combined pyrite and arsenopyrite abundances ranged between 5-30% and yielded 3.14 g/t Au over 3.2 metres (Table 3). Weakly mineralized greywacke and iron formation comprised the remainder of the hole and returned low gold values.

09S019: Hole 09S019 was dominated by greywacke in the upper 57 metres of the hole with minor alteration and low gold values. Proximal to the iron formation contact, sulphide abundances increase sharply (pyrite up to 10%) with increased alteration and a consequent gold intercept of 1.54 g/t Au over 2.15 metres including a single sample of 6.3 g/t over 0.39 metres. Weakly mineralized greywacke and iron formation comprised the remainder of the hole and returned low gold values.

Drillhole Number	Easting	Northing	Depth (m)	Azimuth (deg)	Dip (deg)	Year

Interpretations and Recommendations

Based on favourable drilling results, additional work on the Pillars property is warranted. The following recommendations are made to help guide future exploration on the property

1) A professional structural geologist should spend a few (4-5) days on the property to gain a better understanding of the structural history of the area and how it controls gold mineralization. Time should also be spent looking at drillcore, with particular emphasis on the oriented structural data that was gathered during 2009's drilling program. This information should be used to help guide future drilling on the property.

2) More time should be spent trying to locate old INCO drill collars to tighten up the 3-D modeling of the deposit, which integrates the work of INCO, Kodiak and Sage. Correlation of iron formation beds at depth should prove useful for determining fold patterns and possibly plunge directions/attitudes.

3) The property should be mapped at a scale of 1:2500 to 1:5000 with an emphasis on the structural characteristics of the property. Detailed mapping of the main stripping should also be completed.

4) Additional drilling on the northern contact zone should be considered. While only sub-gram values were realized in the 2009 drilling, they were over significant (apx. 4m) widths. Furthermore, only two holes were completed along this contact in 2009.

Qualifications

I, Ronnie Therriault, of 120 Banning Street, Thunder Bay Ontario, do hereby certify that:

1) I am a consulting geologist with Sage Gold Inc. with an office at 365 Bay Street, Suite 500, Toronto Ontario, M5H-2V1

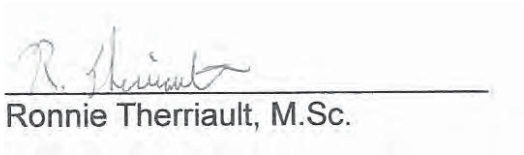
2) I am a graduate of The University of Western Ontario with a B.Sc. and in 2006 with an M.Sc., both in Geology.

3) I have practiced my profession continuously since 2006.

4) I am responsible for, or directly supervised, the writing of this report dated February 5, 2010. It is based on a study of the data and literature available on the Pillars property.

5) As of the date of this certificate, to the best of my knowledge, information and belief, the report contains all scientific and technical information that is required to be disclosed to make the report not misleading.

Dated this 5th day of February, 2010



Ronnie Therriault, M.Sc.

Thunder Bay, Ontario

fine to coarse grained with graded bedding indicating younging to the north, rare pebbly bed at bottom of fining upward sequence, coarser beds tend to be exponentially thicker than fine beds, fine beds display ser alteration locally, 2-5% qtz-carb veinlets throughout interval both following along with foliation and cross-cutting it also see qtz-carb infiling of fractures and tension gashes local stockwork and vein brecciation. Tr py mineralization throughout with rare local concentrations around 0.5%, mainly fine disseminated grains with occasional coarse grains and rare stringers

magnetic with alternating 0.1-1cm bands of he-mg-jasper, variably altered fine to coarse grained greywacke beds between, some beds contain small grey qtz eyes, very few qtz veins and veinlets present all of which seem to be he altered, unit becomes increasingly foliated and local folding is observed down-hole. Minor py (+/- tr asp) mineralization is associated with sandier greywacke beds

alternating fine and coarse grained beds, could be graded but overprinting foliation makes it difficult to determine, unit starts out very bleached/sericitized with intensity fading down-hole,few jasper-he bands near beginning with minor associated py mineralization, foliation increases toward end of interval to gradational contact with schist, very little qtz veining

highly foliated and schistose could be 1c/3c also but not much chl or ser alteration or stringers, cg to fine grained can see reminants of bedding but overprint of foliation makes it difficult to determine if the bedding is/was graded. Locally folded with crenulated layers, few qtz veinlets are also folded/crenulated

17.28	24.64	3b		

fine to coarse grained greywacke with 20-30% iron formation beds composed of alternating thin bands of jasper, hematitie and magnitite, greywacke is varibly altered with zones of chl alternating with zones of ser alteration, most of the chl alteration occures where there is a higher concentration of iron formation beds

fine to coarse grained greywacke with slight ser overprint, graded bedding indicates younging up-hole, coarse grained beds 2-5x thicker than fine grained beds, weakly foliated at beginning but foliation increases down-hole to gradational contact with schist

variably altered greywacke, fine to coarse grained graded beds indicating younging up-hole, dominant alteration alternates from ser to chl and back, zones with ser alteration tend to contain more and larger qtz veins/veinlets while chl altered zones contain jasper-he bands. Minor py and asp mineralization is associated with pinkish qtz veins in ser altered zones
